MASTER'S THESIS

**Tomáš Šíma**

Brno, Spring 2018

*This is where a copy of the official signed thesis assignment and a copy of the Statement of an Author is located in the printed version of the document.*

## **Declaration**

Hereby I declare that this paper is my original authorial work, which I have worked out on my own. All sources, references, and literature used or excerpted during elaboration of this work are properly cited and listed in complete reference to the due source.

Tomáš Šíma

**Advisor:** RNDr. Martin Stehlík

## Acknowledgements

I would like to thank my supervisor RNDr. Martin Stehlík Ph.D. for guiding me and providing technical support for my work.

I would also like to thank Mgr. Jaroslav Šeděnka for his continuous stream of helpful comments and ideas.

Access to computing and storage facilities owned by parties and projects contributing to the National Grid Infrastructure MetaCentrum provided under the programme "Projects of Large Research, Development, and Innovations Infrastructures " (CESNET LM2015042), is greatly appreciated.

## Abstract

We created a tool, which collects data from publicly available social networks and websites related to bitcoin (Twitter, Bitcointalk, Reddit, blockchain.info), online darknet market Valhalla and bitcoin blockchain. The tool imports these data to database, run multiple heuristics and provides user interface for visualizing data and metadata of addresses and identities related to cryptomarkets and blockchain. The tool can for given bitcoin address find the nearest addresses or transactions related to Valhalla drug market or addresses that are mentioned in scraped websites.

To test the efficiency of this tool, we created two profiles on Valhalla cryptomarket and performed multiple transactions to deposit and withdraw bitcoins. We imported into tool the bitcoin addresses of the first profile received bitcoins from and checked, if the tool is able to identify, that addresses owned by second profile had been sending/receiving bitcoin from Valhalla market also.

This thesis has two goals. The first goal is to perform quantitative statistical analysis of Valhalla cryptomarket. We scraped Valhalla cryptomarket website for information about vendors, listings and buyers and brought up a lot of interesting statistics about them.

The second goal of this thesis is to create a tool to find, analyze and visualize publicly available data, which can be helpful to deanonymize users of drug markets available via Tor on dark web. The aim of this tool is to help investigators with collecting intelligence about entities related to these drug markets. Users and operators of these markets employ multiple means to prevent their deanonymization. Cryptomarkets are operated as Tor services, PGP encryption is often required to communicate between multiple parties and bitcoin is used as a way of paying for goods or services.

# 1 Introduction

The relative anonymity of the Internet offers an incentive for criminal parties to use the Internet as a tool for their activities. Internet facilitates some forms of existing crimes (selling drugs, guns and counterfeits, running Ponzi schemes) and also enables many new types of frauds like hacking, phishing and identity theft.

Publicly available statistics show that cybercriminals are much less likely to be discovered and persecuted than criminals operating offline. In the USA in 2010, there were 5628 robberies and the loot was recovered in more than 20% cases. [fbi10] In the same year FBI received 303809 complaints related to cyber crime, resulting in just 6 convictions. [fbcyber] Criminals value their anonymity very highly and use various means to prevent being caught by police forces. [tzanetakis2016transparency] [van2013surfing] [aldridge2014not]

A big problem for criminals was getting the money they got from criminal activity to their possession, since that required some form of physical presence or identification. Also, it was hard for two anonymous entities engaging in criminal activity to transfer value to each other, because it's hard to set up an anonymous bank account and neither party could be sure about the origin of the money they have received.

For bitcoin, there is no central authority requiring bitcoin address (bitcoin equivalent of bank account number) to be linked to person's identity and so criminals can just use their connection to the Internet to both receive and send bitcoins without disclosing their identity. However, all bitcoin transactions are publicly available and so each bitcoin can be tracked through the whole transaction history.

Cryptomarkets are online marketplaces, where vendors offer illicit goods and services. Cryptomarkets are accessible via Tor network as an .onion service, users of cryptomarkets use PGP to communicate with each other and use bitcoin as a way to transfer value. These mechanisms make it possible for cryptomarkets to publicly operate, yet be hard to reach by law enforcement. [cox2016staying]

We scraped and examined data from Valhalla market, to our best knowledge one of the most popular and well established currently

(February 2018) operating drug markets, in order to do a statistical analysis of the scale of its operations.

All the bitcoin transactions are stored in blockchain. Blockchain is publicly available, and so anyone can access data about bitcoin transactions. Bitcoin transactions transfer bitcoins between bitcoin addresses. It is common practice for users to generate new bitcoin address for each incoming transaction. When user pays via bitcoin, he might use bitcoins just from some small subset of his bitcoin addresses and so the recipient doesn't know about sender's addresses that were not used in the transaction. This mechanism helps sender not disclose how many bitcoins he owns in total and also protect receiver from finding all transactions that were done by sender in the past.

## 1.1 Goals

We created a toolchain for drug market users deanonymization by using publicly known data. The tool imports bitcoin blockchain into neo4j graph database in order to create a graph of transactions. It then runs multiple heuristics over this graph to cluster addresses that belong to the same user. The tool scrapes multiple public sources related to drug markets and bitcoin transactions in order to obtain some form of identification(username) linked to bitcoin address and adds this information to database. It provides GUI where user can insert address and the program finds addresses with linked identities that are few transactions away from the inserted address in the transaction graph. We also created multiple scripts for scraping information about trades from Valhalla market website and export them to .csv files and used these data for quantitative analysis of Valhalla market operations.

## 1.2 Structure of the thesis

Chapter *related terminology* starts with a quick introduction on how cryptomarkets work and the technology they use. It continues with describing the major technologies used by cryptomarkets – bitcoins,

Tor and PGP. Chapter *Related work* gives an overview of previously published works on similar topics.

The chapter *Methods and tools of data retrieval and analysis* describes the process of collecting and storing the data from bitcoin blockchain, drug markets and publicly available forums and social networks.

The chapter called *Application for searching nearby identified addresses* describes the functionality, architecture and implementation of the application that was created as part of this work.

Chapter *Statistics of Valhalla cryptomarket* consists of various statistics about drug markets that were gathered by Valhalla market website scraping.

*Testing and verification* chapter is about the testing of the created application. The last chapter is a discussion about achieved goals, problems of implementation and possible future improvements.

Chapter *Conclusions and future work* discuss achieved goals and possible future extension and development of this work.

## 2 Related terminology

In this chapter, I explain the terms and technology related to online drug markets. Online drug markets use several technologies that are crucial to their anonymous operation. Bitcoin enables different parties to exchange value in an anonymous way. Tor allows users and administrators of a marketplace to hide from any third party doing packet sniffing on the network, that they are accessing drug marketplace. It also hides the location on drug marketplace web server from its users. PGP enables sellers and vendors to communicate between each other in an encrypted way, so that drug market administrators cannot eavesdrop on that communication.

### 2.1 Cryptomarkets

Illegal online markets have been around for more than 30 years [**motoyama2011analysis**]. On these markets, users can sell and buy drugs, weapons, hacking tools, stolen credit cards, counterfeit currency, forged documents and other illegal goods and services. Most markets forbid selling the most unambiguously harmful goods, such as child pornography or hitman services.

In 2011 there appeared a new type of illegal online marketplace called cryptomarket. A cryptomarket is an illegal online market accessible only via Tor network and using bitcoins as a means of making payments. These two technologies provided a safer environment than previous markets hosted on forums and chatrooms.

Physical products, like drugs, are sent to a buyer via ordinary mail to the address provided by the buyer. The package is disguised as packages containing common goods sent by big online retailers. [**paquet2017cryptomarkets**]

Cryptomarkets are popular with vendors, because they offer them high influx of customers and secure and anonymous environment for conducting their business [**van2014responsible**]. Cryptomarkets offer safer, more comfortable and more professional way of buying drugs, avoiding the need to meet face to face with dealers [**barratt2014use**].

Nowadays, there exist multiple cryptomarkets competing against each other and the risk of a failure of a deal is still high [**wehinger2011dark**].

In order to protect buyers, cryptomarkets use Escrow and vendors' feedback to identify scammers and minimize losses. Silkroad cryptomarket used Tumbler services [ron2014did], which makes it harder to analyze bitcoin transaction graph. Valhalla cryptomarket claims that they users can withdraw bitcoin from them using bitcoin tumbler too.

### 2.1.1 The process of ordering

Most of the cryptomarkets are publicly available and there is no fee for creating a user account. The act of buying drugs from them is considered user-friendly by buyers and is similar to the process of buying goods from popular lawfull e-shops like Amazon.

The whole process consists roughly of these steps:

1. User creates an account on cryptomarket if he doesn't have one already
2. He tops up his account by sending bitcoins to the bitcoin address, that was generated for his deposits.
3. He than finds an offer that he is interested in and buy it in a similar way as in any other e-shop.
4. Buyers' money is now locked by cryptomarket.
5. The buyer and vendor communicate out the way of delivery.
6. If the buyer receives goods or services, he confirms it and money is unlocked to the vendor.
7. Buyer gives feedback to the vendor.
8. Vendor withdraw bitcoins from the market to his bitcoin address.

Vendors value their feedback ratings very highly, so they encourage buyers to leave positive feedback when the transaction goes well.

Table 2.1: Visited cryptomarkets

Cryptomarket name	Number of listings
Dream Market	72830
Valhalla	25309
Wall street market	10566
Point market	9202

### 2.1.2 Valhalla cryptomarket

We selected Valhalla cryptomarket<sup>1</sup> based on three metrics. The first metric is its size.

We checked list of active cryptomarkets mentioned on reddit community *r/darknetmarkets* and website *https://www.deepdotweb.com*. The site *https://www.deepdotweb.com* has alexa ranking 23500, which roughly corresponds to thousands visitors a day. The reddit community is the first link for google query "darkmarkets list" and has more than 160 000 readers. The webpage So we consider these sites to be relevant enough to not miss the biggest cryptomarkets in their lists. Cryptomarkets taken into consideration are in table 2.1.

Valhalla market is well known operating cryptomarket. With more than 20 000 active listings and 900 vendors, it's the second biggest currently operating cryptomarket.

Among these cryptomarkets only Valhalla and Dream market has been operating since 2013. This is to advantage of our analysis, as we can analyze matured cryptomarket with vendors, who have been selling for a longer time and have more reviews.

Among cryptomarkets mentioned above, Valhalla cryptomarket provides the most information about vendors and buyers. Each feedback for given vendor consists of buyer's comment, date the feedbacks were given, the listing the user gave feedback to, the sum of money the buyer spent on market, the amount of trades the buyer did on the Valhalla market and first and last 2 digits of the buyer's nickname. (eq. for buyer with nickname "gopnik789" it shows "go\*\*\*89")

1. Available at <http://Valhallaxmn3fydu.onion>

The 2 first and last digits of buyer's username are really unique for Valhalla market, other markets offer first and last character of buyer's username at most. This will drastically help with recognizing the same buyer among multiple feedbacks. Valhalla is also the only market from the markets above, where customer feedback also contains the associated listing. This allows us to detect the most profitable and popular listings.

### 2.1.3 Vendor's feedback

Cryptomarkets usually employ reputation systems [resnick2000reputation], where buyers can share their satisfaction with vendors. These systems are similar to systems used in popular e-commerce websites like Amazon or Ebay. Users can give feedback only to vendors they have traded with. On some cryptomarkets, it is only possible to upvote and downvote vendors, on some others, people can rate different parts of their interaction with the seller, like the easiness of communication, the speed of sending the goods and unsuspectingness of packaging.

Feedback is not mandatory, but vendors encourage buyers to give them positive feedback [aldridge2014not][soska2015measuring], because the positive feedback ratio gives the vendor a significant advantage over vendors with worse feedback.

## 2.2 Bitcoin and blockchain

Bitcoin [nakamoto2008bitcoin] is the first decentralized peer to peer cryptocurrency, created by the anonymous author(s) known by pseudonym Satoshi Nakamoto in 2008. Bitcoin transactions are not verified by central authority, they are processed by distributed peer to peer network of bitcoin nodes instead. The source code of bitcoin nodes is an open source and can be downloaded and run locally. The entire history of transactions is stored in a distributed public ledger called blockchain. Bitcoin combines multiple cryptography algorithms to achieve consensus among nodes on the state of the blockchain. The state of blockchain is protected by the computing power of bitcoin miners using cryptography to validate and add new transactions. State of blockchain should only be modified by adding the new block of transactions to the

end of the clockchain. Third party attacker could theoretically modify blockchain if he had 51% of the whole mining computing power. This has nearly happened once, mining pool Ghash.io accounted for more than 42% of mining power in 9.1.2014. In reaction to that event, some of miners mining under this mining pool leaved pool in order to prevent this from happening. Also, it sometimes happens, that two miners add different new block to the blockchain at the same time and for some time, there exist two versions of blockchain with different last block. These two versions exist until the next block is found for one version. Miners than accept the longer chain of the two versions and the shorter one is discarded. It is therefore recommended to wait multiple blocks after the transaction is added into blockchain to be sure it does not disappear by this forking.

### 2.2.1 Addresses, bitcoins and transactions

In order to receive and send bitcoins, a user needs to have a bitcoin address. A bitcoin address is a BASE58<sup>2</sup> encoded public key with 4 bytes added for checksum. Each address has its associated private key. In order to send bitcoin from bitcoin address, a user needs to have a private key associated with the given bitcoin address. Storage and usage of bitcoin addresses and associated private keys is automatically managed by software called bitcoin wallet. There exist many third party software wallets.

All the transactions, bitcoins and addresses are stored in the blockchain, the transaction history with all data about transactions is publicly available. When someone pays by bitcoins, the recipient can see the recipient address and can search blockchain for all transactions the sender address was part of. In order to not see the whole history of transactions and balance of the address owner, the bitcoin wallets generate a new bitcoin address for each transaction where owner receives bitcoins. When spending bitcoins, the software uses subset of the previously generated addresses and can spend bitcoins from multiple addresses in one transaction. Therefore, when pairing the address to identity, we can directly obtain just the history of transactions related

---

2. <https://en.wikipedia.org/wiki/Base58>

to the given address, but not all transactions and balances of the user, as he is likely to own multiple bitcoin addresses.

Bitcoins in blockchain are represented as inputs and outputs of the transactions. Each transaction has some inputs and outputs. Input and output is the same data structure, it only differs in its relationship to the given transaction. Each input/output consists of its unique identifier, its value in bitcoins, bitcoin address that owns it and a script that describes, how the input/output can be used. The scripts allows for greater flexibility in transactions. The script can define, that for spending given output two private keys, or combination of several keys is required.

Every output can be used exactly once as an input of a new transaction, and therefore the owner of an output can not spend one output multiple times. He also can not directly spent just a portion of bitcoins from the output. In order to divide bitcoins in smaller parts, he needs to use "change" address. The change address mechanism is described later. When the sender sends a bitcoin to the recipient, he generates a transaction and sign it with required private keys . The new transaction must comply with the following:

- The scripts of all used inputs trigger no failures and return True  
= The sender is authorized to use inputs
- No input has been used as an input in any other transaction =  
The sender cannot spend one output multiple times
- The sum of bitcoins of transaction inputs is equal to the sum of bitcoins of transaction outputs + fees

The new transaction must have 1 or more outputs. There can be multiple outputs in a transaction with different associated addresses and bitcoin value, however, there happens to be a common pattern. When the sender sends bitcoins to one recipient, the transaction typically contains two outputs. First output contains the recipient's address and the volume of bitcoins he receives. Second output is called *change output*. Since the sender usually doesn't own outputs with exactly the amount of bitcoins he wants to transfer, he adds a change output to the transaction. The change output's associated bitcoin address is owned by sender and so the sender get's back the bitcoins that he doesn't

want to transfer. This is the only way to split bitcoins into smaller parts. Schema of transaction where sender spends output worth of 5 bitcoins and sends 2 bitcoins to recipient and get 3 bitcoins back is on figure 2.1

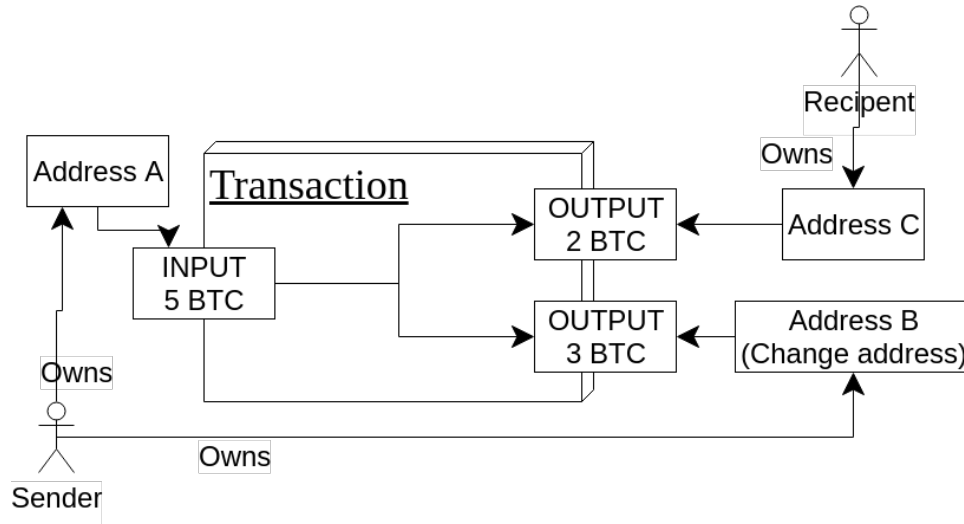

Figure 2.1: Mechanism of change address

When sending bitcoins from bitcoin wallet, wallet software creates transaction data and signs it with required private keys. Then it sends it to one or multiple bitcoin nodes. Nodes collect transactions from users and broadcast them to other nodes on best effort basis. The validity of the transaction is later checked by miners and added to the newly generated block in blockchain.

### 2.2.2 Mining

The purpose of miners is to verify transactions and protect blockchain from being overwritten by malicious third party. Miners are running bitcoin nodes and mining software, which enables them to create a new block of transactions, add it to blockchain and broadcast a new, longer version, of blockchain to other nodes. Finding a new block of transactions is a hard problem from computational perspective. The SHA256 hash of newly generated block must be lower than given number called difficulty. The lesser is the difficulty, the harder is it to find the new block. Difficulty is adjusted every 2016 blocks in order

to match the computational power of miners, so that new blocks are generated on average once per 10 minutes.

Each block must contain the hash of the previous block in the blockchain, so it is impossible to precompute the problem for blocks that will come further in the future. Each block besides other things contain list of transactions and some free space, where miners can insert random data to change the hash of the block. Miners try to find block that satisfy SHA256 requirement by brute-force by filling this space and when they find a solution, they are able to generate a new block of transactions and broadcast it to other miners. When miner generates a new block, he can claim all of the fees of transactions included in that block, also he is able to create a special transaction called coinbase transaction that sends bitcoins from nowhere to his address. By these coinbase transactions, new bitcoins are emitted into the network. Blocks are limited by size and therefore may contain limited number of transactions. It is possible for new transactions to be waiting for being added to the blockchain for some time, because miners prefer to add transaction with higher fees to the next block.

### 2.2.3 Tumblers

Anyone can download blockchain and therefore obtain information about all bitcoin transactions that ever happened. It might seem that bitcoin transactions are anonymous, but when the user sends bitcoins to someone(exchange) who knows their identity, the recipient can pair the bitcoin address the bitcoins came from to the identity of the sender. Although bitcoin users usually use multiple bitcoin addresses, their transactions and addresses are still susceptible to some analysis of blockchain transaction graph. This might identify other addresses belonging to the owner of the address we already know.

Bitcoin Tumblers exist in order to prevent or at least obstruct such analysis. A user sends bitcoins to the tumbler service and the service mixes his bitcoins with bitcoins of other users by performing multiple transactions between its bitcoin addresses. [moser2013inquiry]

The structure of these transactions differs for different tumbler services. The user sends their bitcoins to an address owned by the tumbler, then he generates a new, never used bitcoin address. He then receives bitcoins from tumbler service to his new bitcoin address.

There also exist peer-to-peer tumblers(CoinJoin, SharedCoin, Coin-swap), that enable multiple users to directly create transactions to mix bitcoins among themselves. These transactions can be performed multiple times with different actors.

### 2.3 Tor - the onion routing

Communication between browser and web server is usually done via HTTPS protocol. This protocol uses asymmetric cryptography. The web server and browser exchange their public keys at the start of communication and encrypt the data using these keys. Decrypting the data is possible only by corresponding private keys, which the browser and web server keep locally. This protocol is susceptible to man in the middle attacks. If the attacker has control over the transmission from the start of communication, he can place himself in the middle of communication and act as a web server for the user and as a user for the web server. To prevent these types of attack, a certification authority is needed. The certification authority is an institution that signs public keys, belonging to the web server. When the browser receives the public key, it automatically checks, if it is signed by any authority from its list of authorities and if not, it displays a warning or error message. The HTTPS protocol encrypts data, but doesn't hide the identity of the user from the web server, and also the Internet provider can see, where is the user connecting. Tor aims to solve these issues.

Tor [dingledine2004tor] is a free open source software that provides access to Tor network. Tor network is a network of Tor nodes. The goal of Tor project is to provide its users encrypted access to the Internet in order to prevent third parties from eavesdropping and analysis of the transmitted data. The usage of Tor can be detected by the third party, but the third party can not decrypt user's data that are transmitted via Tor. Some websites restrict access from Tor networks due to many risks involved. Tor hides user's identity from the web server. Also Internet provider can just detect that user is connecting to Tor , but can not identify the other side of communication and content of the transmitted data.

The simplest way for user to use Tor network is to install Tor browser bundle, which consists of modified firefox browser and onion proxy. Onion proxy routes all traffic through Tor network. Tor network consists of more than 6000 publicly available TOR nodes(also called relays or routers). Anyone can run a Tor node, but there exist a subset of specialized servers called directory authorities, Directory authorities monitor relays and distribute a list of relays that are working and not under the same IP address. Tor nodes splits into 3 groups, guard nodes, relay nodes and exit nodes. A client achieves anonymous communication by proxying his traffic through a chain of 3 Tor nodes, so called circuit, as it can be seen on picture 2.2. Client obtains public keys of these 3 Tor nodes from directory authority and negotiate symmetric keys for encrypting the data with each node. When client wants to send some data, he split them into fixed size chunks called Tor cells and encrypt them with multiple layers of encryption by the symetric keys negotiated in previous step. The schema of the encrypted Tor cell is on picture ?? Each node in the circuit decrypts the Tor cell and therefore removes one layer from it. The exit node decrypts the last layer of encryption, reads the original data of the client and sends the packet to destination address. The reponse is than again encrypted by symetric keys and sent back by the same circuit. This way, each node only knows it's neighbours in the tor circuit, but doesn't know the rest of the circuit. Tor employs multiple additional features for Tor relay selection and circuit building to prevent attacks by behaviour and statistical analysis.

Cryptomarkets are running as a hidden services on TOR network. Tor hidden services is a feature of Tor for providing a service (e.q. a webserver, IRC server etc.) over Tor network without disclosing the server's IP address. The hidden services have special top level domain .onion.

When administrator of service wants to be accessed, he crates a RSA keypair. The public key in base-32 encoding is identifier of service and service can be accessed by accessing URL identifier.onion. The administrator choose some Tor nodes as introduction points and establish a circuit to each on of them. The administrator than upload a descriptor of the service to 6 different hidden service directories(HSDir). HSDir is a Tor node with a special flag that was assigned to it by TOR authorities. The selection of HSDirs changes every 24 hours and can be

Figure 2.2: Tor routing schema

deterministically computed from time and hidden service public key. The descriptor contains the hidden service public key and signed list of introduction points.

When client starts connecting to the hidden service, he uses service's domain name(= public key) to compute HSDirs with service descriptor. It download a service descriptor from HSDir with list of introduction points. Client also generates one time secret, pick a random Tor node, asks it to act as randevouz point and tell it the one time secret. Then client sends to introduction point a message for the service(encrypted by service's public key) with the information about randevouz point and one time secret. The service recieves the message, connects to randevouz point and uses one time secret to match with client. Randevouz point than just relays messages between client and hidden service. All the connections mentioned above can be seen on picture ?? . Note that there is no direct connection between two servers during hidden service set-up, all communication between servers are routed through regular Tor circuits. Randevouz point just act as a relay between two Tor circuits.

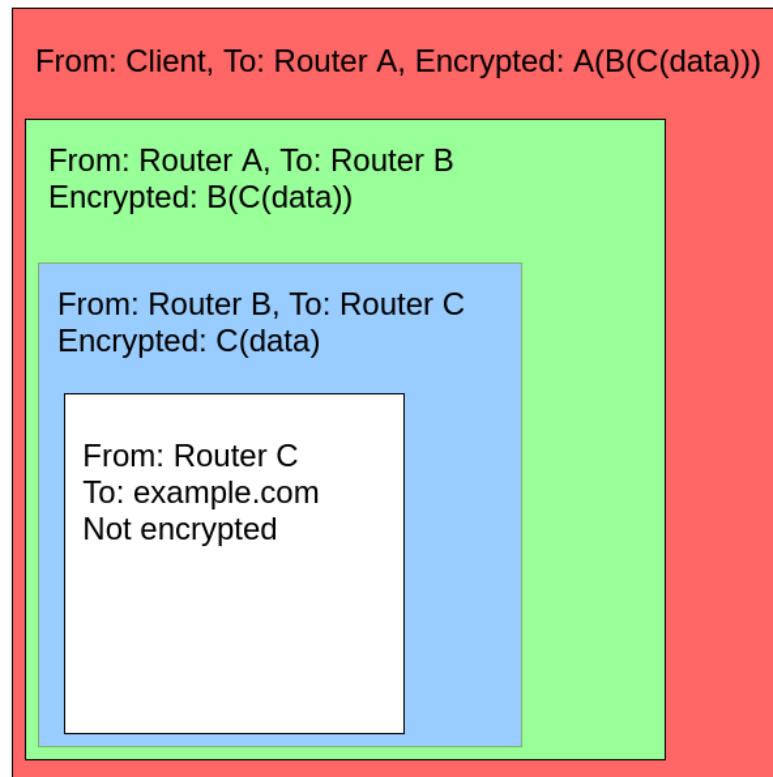

Figure 2.3: Tor packed encryption schem

## 2.4 PGP

PGP [Zimmermann:1995:OPU:202735] is a program for encrypting data and communication between two parties using public key cryptography. PGP is used for signing, encrypting and decrypting messages, mostly e-mails. PGP was developed in 1991 as an open source, with the intention to provide an open, widely used standard for encrypted communication. Nowadays, PGP program is not an open source anymore, but the standard is used by open source GPG software.

PGP uses public key cryptography. Unlike symmetric cryptography, public key cryptography uses two different keys for encrypting and decrypting. A user generates a pair of keys, a public key for encrypting emails sent to him and a private key, which the user keeps

for himself and uses for decrypting messages encrypted with the associated public key. The user also publishes his public key, so other users can send him encrypted messages.

PGP is used in the context of online drug markets as a means of secure communication between vendors and customers. Both vendor and customer have their public keys published on their profile page and use the public key of the other party to encrypt messages to them. This enables vendors and sellers to keep their communication private also from the administrators of the marketplace.

## 3 Related work

### 3.1 Blockchain analysis and de-anonymization of bitcoin addresses

Multiple papers and tools were published regarding the analysis of blockchain. Blockchain contains all bitcoin transactions and anyone can simply check the source and destination addresses of every transaction in the system. It is heavily encouraged for users of blockchain to use multiple bitcoin addresses and every major bitcoin wallet (software, for receiving and sending bitcoins) do so. It is therefore useful to detect addresses belonging to the same user.

The authors of first research article [**reid2013analysis**] parsed blockchain files to create a graph of bitcoin transactions, with vertices as transactions and edges between them represented bitcoins flowing from one transaction to another. They created so-called user graph by clustering addresses belonging to the same user. They used simple heuristics that the owner of all input addresses used in a transaction must be the same. The first version of this article was published in 2011 and dealt with a much smaller number of people using bitcoin and smaller transaction graph. Their analysis also focuses on deanonymization through multiple aspects of bitcoin protocol, while this thesis focuses on deanonymization from transaction graph and public data.

Androulaky [**androulaki2013evaluating**] performed clustering using two heuristics. The first one is the same as [**reid2013analysis**] did that all inputs of transaction belong to the same user. The second heuristics is clustering some outputs of the transaction with its inputs. Most transactions have two outputs, one is owned by the transaction recipient, the other one is called change output and is owned by the sender. The mechanism of change output is described in chapter 2.2.1 and the heuristics in chapter 4.4. If the transaction has two output addresses A and B, A has appeared in blockchain before and B not, then he assumes that B is the change address, because it is common for wallet software to generate new never used addresses for change outputs. They also employed multiple clustering techniques based on the behaviour of users. They tested the success of their clustering techniques in their simulated bitcoin environment.

Advanced and similar work was done by [spagnuolo2014bitiodine]. They downloaded the blockchain, transformed to the database and performed clustering to get a graph of transactions between users. Then they developed a tool, which scraped data from multiple locations(Bitcointalk and bitcoin-OTC forum) to link off-chain data and identities to bitcoin addresses. They tested the tool on few popular transactions related to the seizure of Silkroad marketplace.

Similar work to this thesis was done by [fleder2015bitcoin]. This paper use data from Bitcointalk, the most popular bitcoin forum. They apply a simple algorithm to group multiple bitcoin addresses belonging to one user together. Then they use the scraped data to show that some of the Bitcointalk users were using Silkroad marketplace or other popular services accepting bitcoin.

Ron and Shamir [ron2013quantitative] focus on bringing interesting statistics about bitcoin transaction graph and provided a detailed analysis of really big bitcoin movements ( more than 5000 BTC) through transactions in the network. In their other study [ron2014did], they analyzed transactions performed by Ross Ulbricht, who was the administrator of Silkroad marketplace. The FBI published their bitcoin address, which they used to collect all seized bitcoins from Ross Ulbricht. They took the size and frequency of transactions related to the seized bitcoins prior to the seizure and compared it to the estimated income of Silkroad. They found discrepancies between the relatively stable income of Silkroad marketplace and unstable balances in bitcoin addresses that were seized by FBI. They conclude that FBI seized around 22% of Ross Ulbricht bitcoins and found addresses that posses a some of these bitcoins, which has not been used since Ross' arrest.

In contrast to previously mentioned papers, Meiklejohn [meiklejohn2013fistful] doesn't only passively scan blockchain, they actively send bitcoins to addresses of well-known services to track their bitcoins in the following transactions executed by the service. They also used the same two heuristics for clustering addresses as Androulaki. [androulaki2013evaluating] They concluded that the network does not offer enough anonymity and large transactions can be traced.

All of the previously mentioned works had to deal with much smaller transaction graph, as the usage of bitcoin grew significantly over the last year. To the best of my knowledge, no previous work utilizes so many resources of data as this work. Also, the aim of our tool

is to be able to detect, if some specific bitcoin address of investigator's interest was somehow connected to Valhalla drug market, or at least find nearby deanonymized addresses in the transaction graph to help with further investigation.

### 3.2 Behaviour of drug markets users and operators

Emerging cryptomarkets brought the attention of the scientific community and lots of articles have been published related to the phenomena of drug trafficking via the Internet. Most of these papers were investigating the topic from the social and criminology perspective and performing qualitative analysis. [aldridge2014not] [barratt2014use] [christin2013traveling] [dolliver2015criminogenic] [van2013silk] [walsh2011drugs] [martin2014lost]

There are only a few articles focusing on statistically describing fully operating drug market and its vendors by collecting and analyzing data from a cryptomarket webpage. Short description of works like that follows. Aldridge [aldridge2017delivery] scraped Silkroad in September 2013, the most popular cryptomarket of that time. He focuses on how the vendors and buyers perceive a risk of arrest and attempt to limit them. He concludes that users of cryptomarket are aware of the risks both related to their physical and online activity and actively reduce their risk.

Decary [decary2017repeat] focus on answering the question, how loyal are buyers on cryptomarkets to vendors. It seems, those popular vendors successfully build their loyal customer base. These findings make sense, given the natural health risks related to using drugs, customers prefer vendors with high reputation and trust.

Broseus [broseus2016studying] restricted his research to vendors shipping from Canada and track their activity through multiple markets. His findings include that same vendors use same usernames and sometimes PGP keys on multiple marketplaces because reputation is highly valued in these cryptomarkets and so vendors try to keep it when moving to the new marketplace. Also by his findings, some vendors are highly specialized in selling on the category of drugs, while others offer a wide range of drugs.

Article by Doliver [[dolliver2016characteristics](#)] is most similar to this work. They scraped and analyzed two popular cryptomarkets, Agora and Evolution and quantitatively assess the characteristics of vendors from both markets, focusing on the difference between different markets' vendor populations.

All previously mentioned works were analyzing cryptomarkets that are not operational nowadays, while this work focus on describing the vendors from currently operating drug market Valhalla and examine, if the behaviour of vendors or the nature of cryptomarkets has changed significantly. We also not only passively scraped cryptomarket's webpage, but also created a user account on the marketplace and sent/received bitcoins from the marketplace in order to get data about the cryptomarket's flow of money.

## 4 Methods and tools of data retrieval and analysis

### 4.1 Valhalla cryptomarket webscraping

We scraped data from Valhalla cryptomarket during january and february 2018. We used official Tor daemon and software called privoxy, to create a local proxy that will redirect all incoming traffic through Tor network. The privoxy was needed because Tor daemon creates SOCKS proxy, which can not be used by wget. So we created an HTTP proxy by privoxy, which redirected the traffic through Tor SOCKS proxy. we did not have to implement any login and captcha solving functionality for web scraping Valhalla market, because all the webpages about market listings, vendors and feedbacks are available without logging in.

Addresses of all market listings are in pattern `http://Valhallaxmn3fydu.onion/products/xxx` where `xxx` is a number incrementing with each new listing. The last listing had number 103770 and only 25309 numbers lead to the valid listing page. Rest of the numbers lead to 404 error. We believe, that these numbers refer to listings that were delisted by the vendor or administrator.

We wrote a small script in bash to iterate through all of the listings and download them using wget command line tool. After downloading all the listing pages, we parsed the downloaded files using python and common Linux command line tools(cat, grep, cut, sed). We were not using python HTML parsing libraries(like BeautifulSoup) for parsing downloaded webpages because HTML elements of Valhalla web pages don't have any unique identifiers and so these libraries bring us no advantage.

By scraping the listings pages, we got unique vendor nicknames, which we used for downloading and scraping vendor's profile and feedback pages. The shortcoming of this method is, that we were able to download and analyze only sellers, that have at least one active listing at the time of data collection. Vendor profile pages were in format `http://Valhallaxmn3fydu.onion/xxx` and their reviews in the for-

Table 4.1: Data scraped from listings

Variable	data type
Vendor's nickname	string
Subcategories	3 strings
Title of listing	string
Price	float

Table 4.2: Data scraped from vendor pages

Variable	data type
Vendor's nickname	string
positive and negative feedbacks	2 integers
revenue	integer $0 \leq x \leq 10000$ USD
PGP key	string, is not mandatory for all vendors
Country	string, country from which vendor ships if available

mat `http://Valhallaxmn3fydu.onion/xxx/palautteet` where **xxx** is a vendor nickname.

From each listing, we parsed:

From each vendor, we parsed:

From feedback page, we parsed the following variables for each feedback:

### 4.2 Valhalla cryptomarket metadata scraping and analysis

We thought that metadata from the photos of drugs, which vendors upload to show in their listing, might contain some information leading to identity disclosure. We downloaded 20 images from valhalla market and examined EXIF metadata using `identify` command line tool.

Only metadata directly depending on image content, like the amount of red, green and blue colours were different for different images. Metadata that could potentially help disclosing user identity, like date of

Table 4.3: Data scraped from feedback pages

Variable	data type
vendor nickname	string
rating	1-5
date	Timestamp, days resolution
buyers nickname	string of length 4
money the buyer spent	int
trades the buyer did	int

creation nad modification, signature and name of software version were the same for all images. The software version contained exactly this string: "ImageMagick 6.8.99 Q16 x86\_64 20170731 <http://www.imagemagick.org>" ImageMagick is popular software library used for manipulating images, so it seems that market automatically rewrite EXIF metadata in uploaded images in order to protect privacy of users. To test this hypothesis, we created vendor account and uploaded an image with custom-made EXIF metadata. We than downloaded the uploaded image from webpage and saw that EXIF metadata were indeed overwritten.

We tested if every transaction that is happening on drug market has its counter transaction in bitcoin blockchain. We deposited some BTC to cryptomarket and bought a licit virtually deliverable product(Guide on weightlifting) and checked if anything happened to the deposited bitcoins. There was no follow up transaction happening for weeks after the deposit transaction was done. This means that markets don't transfer bitcoins when service or goods are bought. All of bitcoin transactions that these drug markets do are accepting bitcoins deposits, sending bitcoins to withdrawing users and possibly bitcoin tumbler transactions, if they use such service. We made multiple deposits and withdrawals from Valhalla in order to track, where were the deposited bitcoins later transfered and where have the withdrawn bitcoins came from. These deposits and withdrawals have been used in our application for clustering bitcoin addresses owned by Valhalla cryptomarket.

We tried to scan ports of drug markets servers and fingerprint their web server, in order to find any vectors for further information gathering. We scanned Valhalla server using netcat and found that the only opened ports are 80(redirect to https) and 443(HTTPS), which is used by web server. The webserver was popular software called nginx, as we detected both from HTTP headers and from webserver fingerprinting tool httprecon. The result of port scan and web server fingerprinting doesn't indicate any new vectors for gathering data about cryptomarket.

Some vendors have published their PGP keys on their profile page. We scraped 150 PGP keys and tested them ROCA vulnerability via python module roca-detect. None of these keys were vulnerable. All these PGP keys were searched for User-Id in metadata and found user-Ids were searched by google. None of the searches for user-Ids(both nicknames and mail addresses) returned usable results. Some of the usernames were just briefly mentioned in some posts on anonymous forums like 4chan.org.

### 4.3 Publicly available data scraping

In order to have some bitcoin addresses and bitcoins linked to identities, we searched Internet for pages, where are bitcoin addresses tied to offline or virtual identities. The sites that we have decided to scrape were Bitcointalk forum, Reddit, Twitter and bitcoin.info. The Bitcointalk is the most popular Internet forums related to cryptocurrencies. URL address of profile page on Bitcointalk and contains the profile number, which starts at 1 and is incremented by 1 for each new profile. It is therefore easy to iterate over all forum's profiles, including the ones with no posts, and check if they have associated bitcoin address. The scripts bitcointalk-scraper.py visit profile pages of all profiles on the forum and scrape usernames and bitcoin addresses. The Reddit and Twitter were scraped by twitter-scraper.py and reddit-scraper.py. The script contain several hardcoded phrases like "Donate bitcoin" and "bitcoind address" and scrapes result of searches for such phrases. Bitcoin.info is a webpage that serves primarily as bitcoin blockchain explorer. Secondary, it gathers multiple statistics about bitcoin blockchain and also offers third parties having their bitcoin address

and identity listed on their webpage. The generated identities are stored as rows in csv files that have 3 columns:

1. bitcoin address
2. URL where was the address scraped
3. nickname of the associated identity

#### 4.4 Using own transactions to identify market wallets

Valhalla cryptomarket generates unique deposit address for each new user. When user wants to buy something, he needs to deposit bitcoins to deposit address, that will top up his account balance and he then uses this account balance to buy stuff. Vendor or user can request withdrawing their bitcoins from cryptomarket and so the cryptomarket decreases their account balance and sends bitcoin to user's address.

For identifying bitcoin addresses that are owned by Valhalla cryptomarket, we deposited small amount of Bitcoins to our user accounts on Valhalla cryptomarket and performed multiple withdrawals by smaller amount than the deposited on to receive bitcoins back. When we requested bitcoin withdrawals, we received bitcoins from different addresses than the deposit one. We consider the deposit address and all addresses we received bitcoins from during withdrawals as owned by cryptomarket.

Knowing just about these addresses would not help us decide if someone sent or received bitcoins from Valhalla cryptomarket. It is common for any service accepting bitcoins to use multiple bitcoin addresses, because it's common practice and even default behaviour for bitcoin core and other bitcoin wallet software. Unique deposit address for each account on Valhalla market is required for each user, so that system can associate bitcoin transaction with Valhalla market account. In order to solve this issue, we used two heuristics that were widely used in previous works [androulaki2013evaluating][reid2013analysis] for clustering bitcoin addresses belonging to same user.

The first heuristic simply states that all inputs of one transaction belong to same user. This is logical, since users generally don't share their private keys and collaborate on creating one transaction. When transaction has multiple inputs owned by different bitcoin addresses, we

assume that all of these addresses are owned by one identity. Schema of the first heuristic is on figure 4.1.

The second heuristic focuses on detecting change address described in chapter 2.2.1. The goal of second heuristics is to detect change addresses in the transactions. When one transaction has two outputs with two different addresses, we assume, that one of them is change address and is owned by the sender. We then search through the blockchain for the first occurrence of each address of the outputs of the transaction. If one of the output addresses had been used before the transaction and second not, then we can safely assume, that the second one is change address[[androulaki2013evaluating](#)]. Schema of the second heuristic is on figure 4.2.

Both of these heuristics are pretty strict and have just a negligible chance of falsely merging addresses not belonging to the same user[[androulaki2013evaluating](#)]. There exist multisignature wallets and also few proposals for anonymization methods that could make these heuristics misleading (like CoinJoin mixer and dark wallet), but these contribute to negligible percentage of transactions.

We measured the success of heuristic clustering in two ways. We had two accounts on Valhalla market, each performing 1 deposit of 0.011 BTC and immediately 10 withdrawals of 0.01 BTC, with roughly 0.001 BTC spent on cryptomarket fees. For the first account, we performed these transactions on 8.2.2018, the second one on 4.3.2018.

We created new bitcoin wallet via mycelium mobile app, deposited bitcoins to it from bittrex exchange and used that wallet only with first account. The second bitcoin wallet was used only by second account and created by coinomi mobile app. Bitcoins were deposited to it from coinmate.cz bitcoin exchange. We installed both these wallets and generated new, never used bitcoin address in each one, and also received bitcoins from two different exchanges in order to not affect our measurement with the fact, that we are owners of both bitcoin addresses.

We then ran our application and looked into the neo4j database, that stored blockchain transaction graph and associated identities. We checked the cryptomarket's address we identified by our deposits and withdrawals, if they were clustered as one identity. The table 4.4 shows, how many identities were associated with given deposits and withdrawals. The heuristics could not associate our deposit addresses,

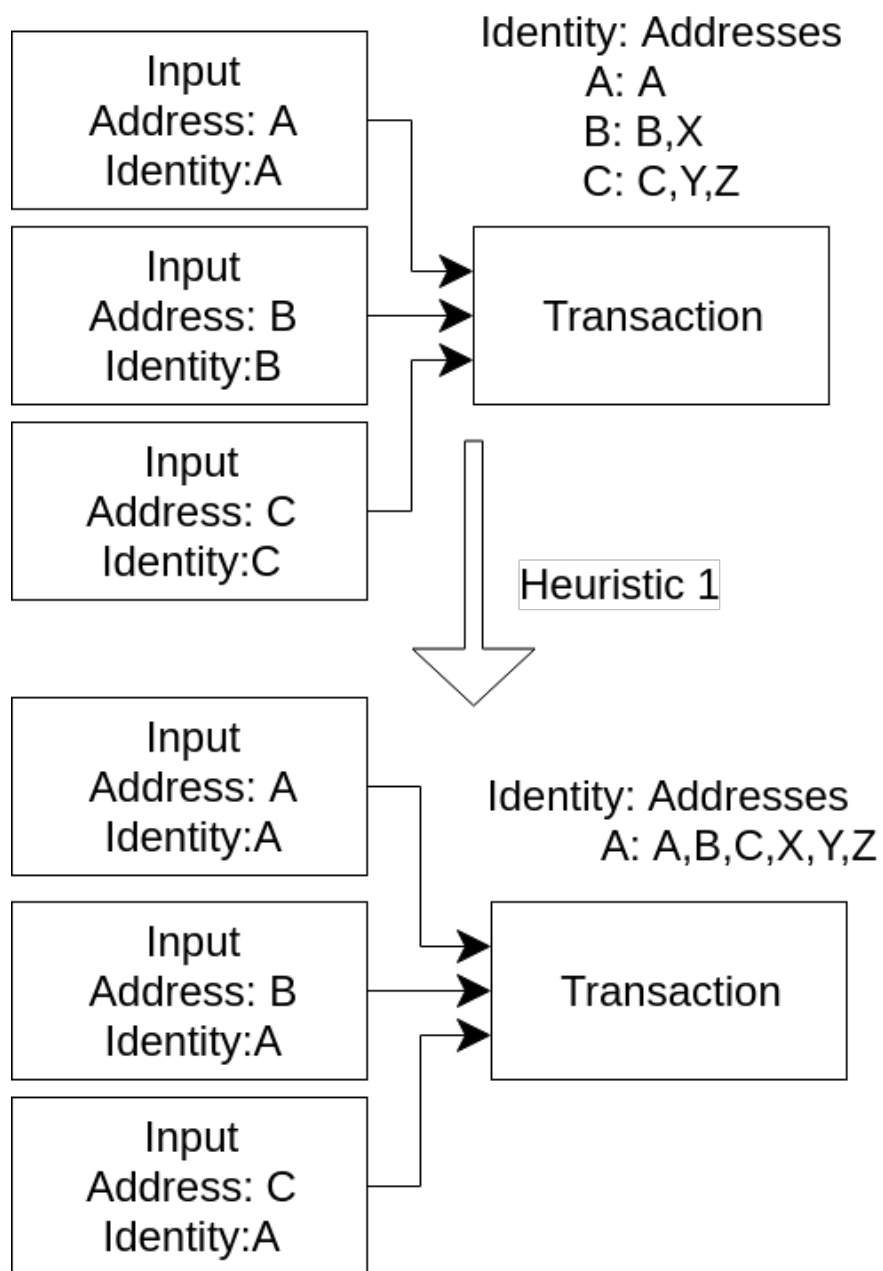

Figure 4.1: Schema how first heuristic works

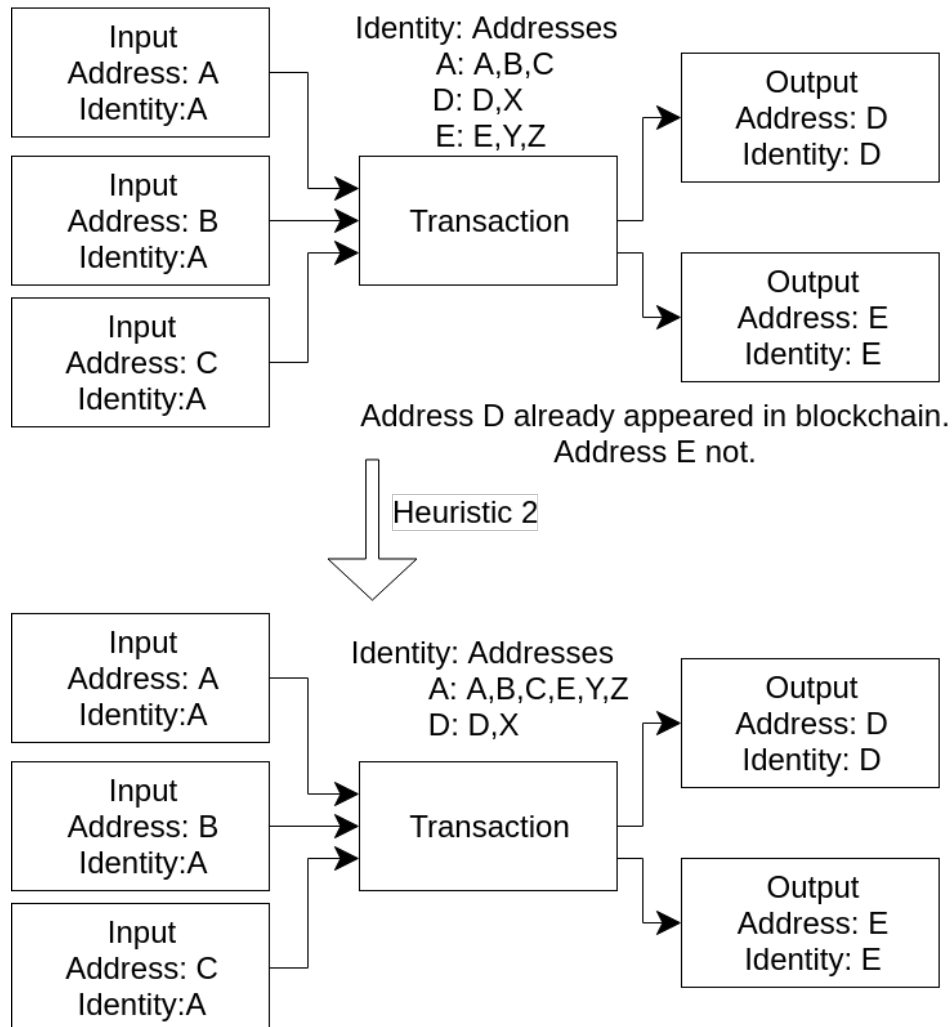

Figure 4.2: Schema how second heuristic works

because the deposit addresses just received bitcoins from us and not sent them somewhere else till that time. Only 2 identities managed to contain addresses from both accounts.

We checked, how much bitcoins have these identities received between 15.1 and 15.2. We scraped Valhalla cryptomarket between 14.2 and 15.2 and we got data from feedback pages, which we used to estimate the minimal amount of bitcoins users spent over the previous month on Valhalla market. We estimated in chapter 6, that users spent

#### 4. METHODS AND TOOLS OF DATA RETRIEVAL AND ANALYSIS

Table 4.4: Mapping of found identities to addresses used in deposits and withdrawals each row in table represent one identity and numbers indicate how many deposits/withdrawals from our accounts were associated with that identity

Identity	Deposits:withdrawals from first account	Deposits:withdrawals from second account	recieved bitcoins
1	1:0	0:0	0.011
2	0:0	1:0	0.011
3	0:4	0:1	2.15
4	0:2	0:0	0.7
5	0:1	0:1	1.5
6	0:1	0:0	0.15
7	0:1	0:0	0.1
8	0:1	0:0	0.1
9	0:0	0:3	1.22
10	0:0	0:2	0.12
10	0:0	0:2	0.37
11	0:0	0:1	0.3

at least 527730EUR during that one month time. With average bitcoin price 8219EUR it roughly equals  $527730/8219 = 64.2\text{BTC}$  The amount of bitcions these identities recieved is also in table 4.4. Our heuristics were not enough to cluster majority of market's transactions/addresses as one identity. Hovewer, with just two accounts, 2 deposits and 20 withdrawals, we were able to identify 5.71BTC(9%) out of estimated 64.2 BTC the market recieved during that one month timeframe.

## 5 Application for searching nearby identified addresses

This chapter describes our application for searching in gathered data. The application architecture is depicted in figure 5.1. It consists of multiple python scripts that falls into 5 categories.

- Scripts for scraping Valhalla market
- Scripts that parse bitcoin blockchain and also scrape data from publicly available sites mentioned in section 4.3.
- The script which imports data to the database, creates indexes and runs heuristics mentioned in chapter 4.4.
- Webserver that handles GUI requests and retrieves data from database.
- The web GUI written in HTML/JS/CSS for sending requests to webserver and visualisation and search in retrieved data.

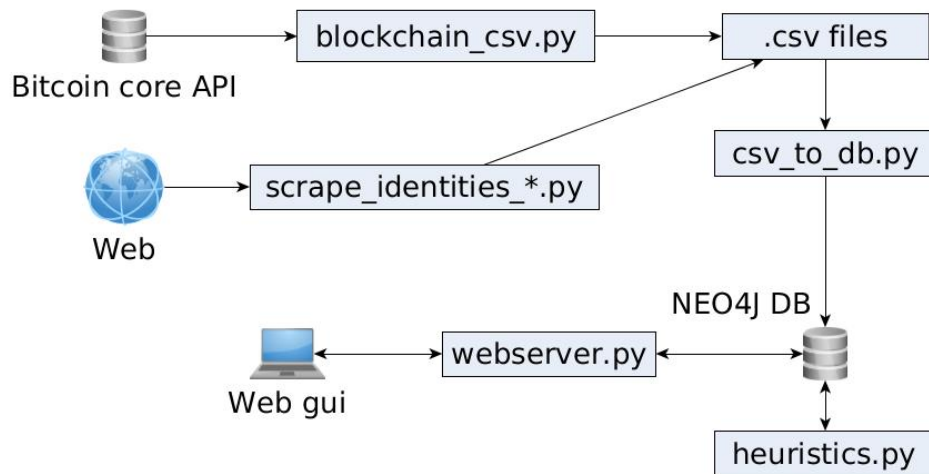

Figure 5.1: Architecture of application

Scripts for scraping Valhalla market in order to get statistical data used in next chapter are in statistics folder. Script *listing-scraper.sh*

goes through Valhalla listings and download the HTML source code of these pages. Script *listing-parser.py* process the downloaded pages and generates file *listings.csv* with informations about listings. *Seller-scraper.py* opens *listings.csv* and downloads HTML source of vendors' profile pages. *Seller-parser.py* process downloader vendor's profile pages and generates *sellers.csv* and *feedbacks.csv*. The variables and data types stored in these csv files are described in chapter in tables 4.1, 4.2 and 4.3. We used these generated csv files for bringing statistics about Valhalla cryptomarket in the last chapter.

The scripts for obtaining data the application needs are in folder *identity-scraping*. Each of scripts named *scraper\_{bitcointalk, blockchain-info, reddit, twitter}.py* scrape webpage mentioned in it's name and generates a csv file with 3 collumns: bitcoin adres, URL where was the address scraped and associated identity (e.q. nickname). Script *blockchain\_to\_csv.py* uses bitcoin-core api to iterate through bitcoin blockchain and generate several csv files with the data about transactions and addresses from bitcoin blockchain that are needed by application. The script generates multiple csv files, that will be later imported to neo4j database, as well as files with identities.

In order to create a tool that will effectively search and visualize blockchain data and the data we scraped from webpages, we need to store the blockchain and identity data locally in that way, so that common graph algorithms, heuristics and searching can be effectively performed. The natural representation of transactions happening between bitcoin addresses is a graph, so we decided to import all the data into Neo4j graph database. It's one of the most widely used graph database with native support for common graph algorithms. Simple representation with addresses as nodes and transactions between them as edges in not sufficient for our case, because we need to represent outputs, inputs and time of transactions in the database in order to be able to compute previously mentioned heuristics. The graph schema is in figure 5.2. The entities in the schema are represented as vertices in the database and relationships between them are edges.

The importing script *csv\_to\_neo4j.py* is responsible for parsing previously generated csv files and importing the data into neo4j database. Having csv files as interminiary step between parsing blockchain and importing it to database is useful for debugging application and also

provides easy way to use application with different blockchain or customly generated data.

Figure 5.2: Neo4j database ER diagram

Script *cluster\_identities.py* connects to database and run the heuristics from the chapter 4.4. It labels each address in our blockchain transaction graph with unique ID representing unique identity. The outputs/inputs owned by the each address are labeled with same ID. Script then runs first and second heuristic, each time rewriting IDs of merged address(and it's outputs/inputs), so that addresses marked by the heuristic as belonging to the same identity have same ID. The *webserver.py* connects to local neo4j database with the schema and data generated by previous scripts and starts local flask webserver that provides web gui on port 5000.

The GUI has one input form, where user should write the bitcoin address he is interested in. The GUI than shows information about the

## 5. APPLICATION FOR SEARCHING NEARBY IDENTIFIED ADDRESSES

inserted address, nearby addresses and found identities. It consists of 3 parts, input form, table and two pie charts. The screenshot of GUI can be seen on picture 5.3. The first part is simple HTML form where user submit bitcoin address he is interested in. After submission, the application search in neo4j data and after a while, the other parts of GUI are updated with information about given address. The table in upper right show list of nearby addresses with known identity. The distance is number of transactions between inserted address and founded address in table. It also shows the URL where the identity was found and amount of bitcoins that were transfered between searched address and address in table. In the lower part, there are two pie charts. The first pie-chart shows the amount of bitcoins that were recieved by the inserted address and what percentage of recieved bitcoins was the application able to link to some identity. The second pie chart shows the same information for outgoing bitcoins, the percentage of bitcoins that were sent from inserted address and ended up in address that we were able to find associated identity.

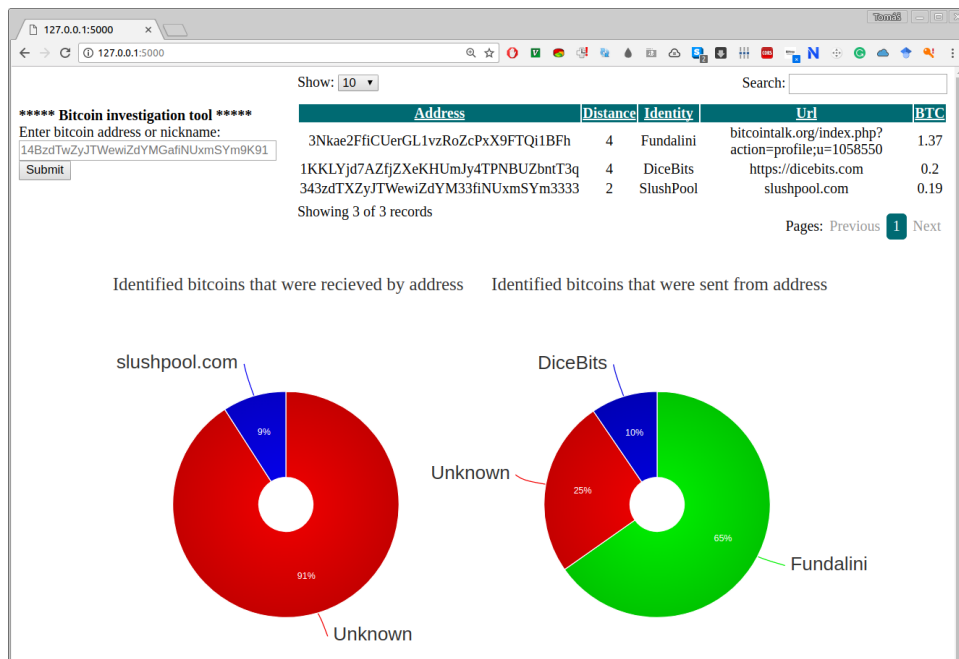

Figure 5.3: Screenshot of Gui

## 6 Statistics of Valhalla cryptomarket

We managed to scrape 25309 listings, 981 vendors and 6381 feedbacks. There were 17314(68%) listings related to selling drug substances, the rest were related to ebooks, premium accounts, guns, fake IDs etc.. Vendors had from 1(90 vendors) to 1083(1 vendor) active listings, with average of 25.69 (SD = 58.06) and median = 11.00 listings per vendor. Most vendors tend to have just few active listings, as it can be seen on histogram 6.1. The histogram does not show 19 vendors with more than 200 listings.

Figure 6.1: Histogram for number of active listings vendors have

Table 6.1: Countries that vendors ship from

Countries vendors are shipping from	Count of vendors
Finland	28
United Kingdom	23
United States	16
Germany	13
Netherlands	12
France	5
Norway	5
Spain	4
Canada	4
Australia	3
Poland	3
Others	31
Unknown	834

Vendors were shipping drugs from 39 distinct countries, the frequency of countries the vendors were shipping from is in table 6.1. Table 6.2 list countries of vendors that have achieved 10000EUR(150 vendors 15% ) or more in revenue. Valhalla was originally established as a local Finnish crypto market, that seems to be the reason for surprisingly many vendors shipping from Finland and also large percentage of Finns among high revenue vendors. They might be on the market since the time it was not internationally popular and had more time to generate revenue.

We looked at total revenue of vendors, which is depicted in figure 6.2a. The total revenue mentioned in the vendor's profile page is capped at 10 000 Eur. There are two major groups of vendors regarded to their revenue. Majority(598 vendors 60%) of vendors have not had any positive or negative feedbacks and all of these vendors but 3 earned less than 300EUR on cryptomarket over their lifetime. Note, that we were able to scrape just the vendors with active listings, so there might be much more vendors who stopped using Valhalla after

Table 6.2: Countries high revenue vendors ship from

Country	Count of vendors
Finland	24
UK	13
USA	10
Germany	6
Netherlands	6
Norway	4
Others	20
Unknown	69

Figure 6.2: Distribution of vendors by their revenue

not being able to earn substantial amount of money. The second group is 150 vendors (15%) who earned 10 000 EUR or more.

Vendors who had high revenue maintained high ratio of positive feedbacks. When counting only vendors with more than 10 reviews (304 vendors 31%), the mean is 93.7% and median 98.3% of positive feedbacks. Vendors with 1 to 10 reviews had on average 27.2% of positive feedbacks. Figure 6.2b shows the the distribution of ven-

dors with similar positive feedbacks ratio and revenue had its LOESS curve. These findings indicate, that market is competitive and having bad reputation during first few sales shuts down any opportunity for the vendor to continue selling his goods and that majority of vendors don't succeed or use market just sporadically.

The figure 6.3a shows distribution of prices of all listings in the market on the left graph and on the right graph is the distribution of prices in feedbacks. Some listings might be counted multiple times or not at all in the right graph, because one listing might be bought several times or not at all and therefore generate multiple or no feedbacks. We expect that distribution of prices in these feedbacks reflects more accurately the prices of the goods or services that are actually bought at market, because feedbacks can be given only by users who bought something from vendor. We calculated price of listings in EUR as price in bitcoin multiplied by the average price of bitcoin for 30 days before the scraping (8219 EUR for 20.1.2018 - 20.2.2018, daily prices taken from blockchain.info).

The average price of listing is 336.2 Eur(1368.2 SD!) with median of 71.3 Eur, while feedbacks had average 82.7Eur(150.7 SD) with median of 55 Eur. There were only 22(0.3%) feedbacks with price > 1000EUR and only 5(0.01%) feedbacks with price > 2000 Eur. There were 1533(6.05%) active listings with price greater than 1000 EUR and 673(2.7%) listings with price greater than 2000 Eur. The price distributions in 6.3a shows, that while there exist a lot of free or very expensive listings, majority(5937, 93%) of trades were between 0 and 200 EUR. There were 115 free listings on the market, but no one of them was mentioned in feedbacks. The free listings had titles like "CARDING SERVICE \*FREE\*", "Free Carding Tutorial 2017" and "FREE SAMPLE 84% MDMA CRYSTAL ROCKS" The titles of expensive listings don't indicate that these listings are somehow special except the price.

We calculated the last month revenue for each category by summing the price over all feedbacks for listings in given category. This leads to minimal revenue, because feedbacks can be given only if the trade happened on cryptomarket and trades happening with no given feedbacks are also possible. The total revenue over one month, amount of listings, feedbacks and market share for given categories is in table 6.3. Market share is a revenue of category divided by total revenue from all categories, which was 527730EUR. Average price of occurred trades

Figure 6.3: Distribution of prices in listings and feedbacks

was similar in each category with two outliers. Opiates, which have the high price/dose ratio and self-defence, which had only 4 trades, 2 of them were custom listings and 2 of them were guns. Custom listings contains no special tag and no description of any goods/services. They contain just titles like "custom listing for Paul", "custom 013" and so on. We found 300 listings with word "custom" in their title. We think that vendors and buyers use these custom listings in order to be able to protect themselves by cryptomarket escrow service for already arranged deal.

Most of the vendors had listings in just few categories. The graph 6.4 shows amount of vendors with given revenue and number of different subcategories they have active listings in. Most vendors sell goods just in few categories, however, vendors with 10000EUR or more in revenue tend to have listings in more categories. The boxchart 6.5 the distribution of vendors revenue based on category they were selling in. We have not count vendors with 0 revenue for the boxchart chart. If vendor was selling in multiple categories, we divided his revenue by the number of categories and counted him in both.

Vendor pages contains counts of feedback gathered over lifetime, these were used in 6.2b. Vendors also has feedback pages, where feed-

Table 6.3: Estimated monthly revenue for selected drug categories based on feedbacks

Category	listings	feedbacks	revenue in EUR	average price in EUR	market share
Cannabis	5139	1883	135693	72	27.6%
Stimulants	3493	1043	108157	103	22%
Opiates	1662	489	83135	170	16.9%
Pharmacy	2294	1104	62054	56	12.6%

Figure 6.4: Amount of vendors with number of different categories they sell and their total revenue

backs younger than 1 month contain first two and last two characters of buyers username, , the rounded total number and price of trades performed by buyer. We used these feedbacks to gather informations about buyers.

There are possible  $36^4 = 1679616$  combinations of 4 alfanumerical characters. From our 6000 feedbacks, we gathered 2433 unique combinations of four letters from username, when added rounded number of trades and buyer's total spending we got 2654. It is highly probable that some different buyers have the same username prefix, suffix, amount of trades and revenue, because when considering buyers total spending and trades, we managed to increase the number of identified buyers. Buyers total spending and total performed trades are rounded just to few distinct values, so the following statistics are just estimates.

Each buyer have bought on average goods for 1176EUR through all his trades on Valhalla market. Just 129(5%) of buyers had bought goods with worth rounded to 10000EUR in total, 1289(50%) buyers

Figure 6.5: How much have Vendors earned based on category they sell

have spendings 500EUR or less. This distribution is similar to revenue distribution of vendors, where vast majority of actors transfer just small amounts of value through Valhalla market and just extremely small percentge of actors trade on market at bigger scale. The average price of the one trade (82.7 EUR) and the average of lifetime spending (1176EUR) is way below the amount someone who actively resell drugs for profit would buy. The distribution of buyers total spending is on figure ??.

Figure 6.6: Distribution of buyers total spending and total performed trades

## 7 Conclusions and future work

We were succesfull with scraping Valhalla cryptomarket and bringing up meaningful and intersting statistics about its vendors and users. Our statistical findings fits into the previously published descriptions of cryptomarkets, but we also found some statistics where Valhalla market is outlier and came up with reasons why is it so. We scraped Valhalla market once, but the data about the feedbacks were related to the time frame of one month. Continously monitoring Valhalla cryptomarket for longer periods of time could enhance the statistical description with data about changes of various trends on this market over time.

Our application is fully working and production ready, it finds nearest addresses with associated identities for given address. The application could be extended in multiple ways. We used two heuristics that have lowest risk of falsely clustering addresses belonging to

different identities. The heuristics have not clustered all the addresses and transactions that have been done by crypto market, however we found, that with just tens of deposits and withdrawals between us and market, we were able to identify significant percentage of cryptomarket's cashflow over given month. The price that we payed in fees in these transaction was altogether less than 100 dollars. Perpetual depositing and withdrawals over prolonged period of time seems financially feasible and might lead to disclosing majority of cryptomarkets addresses and transaction.

Application could be extended by adding more heuristics for clustering addresses. Some of these heuristics have been described in [androulaki2013evaluating]. These heuristics are not based just on graph of bitcoin transactions, but also on expected behaviour of users and data that can be obtained by continously running one or multiple bitcoin nodes. These heuristics are less reliable, but offer more options to cluster addresses of same owner.

The whole application backend can be run on consumer grade notebook. Backend database as indexed and utilizes memory well , requests from GUI takes at most 30 seconds to complete. This is to application advantage, however application set up takes long time, for the simple reason that bitcoin blockchain consists of roughly 150GB of data and these must be inserted into database, indexed and processed by heuristics. For setting the application up on server and having users access it remotely, different options viable for storing and retrieving data on server hardware (for example in memory database if RAM is big enough can be considered.
